Dietary Fatty Acids Directly Impact Central Nervous System Autoimmunity via the Small Intestine

Highlights
- Dietary fatty acids have profound influence on T cell differentiation in the gut
- Middle- and long-chain fatty acids (LCFAs) support Th1 and Th17 cell differentiation
- Short-chain fatty acids (SCFAs) lead to increased Treg cell differentiation
- LCFAs worsen disease in an animal model of MS; SCFAs exert the opposite effect

In Brief
Haghikia and colleagues show that dietary fatty acids (FAs) influence T cell differentiation in the gut, with short FAs leading to increased Treg cell differentiation and long FAs supporting Th1 and/or Th17 cell differentiation. These FAs differentially affect EAE severity, demonstrating a direct dietary impact on central nervous system autoimmunity.

SUMMARY

Growing empirical evidence suggests that nutrition and bacterial metabolites might impact the systemic immune response in the context of disease and autoimmunity. We report that long-chain fatty acids (LCFAs) enhanced differentiation and proliferation of T helper 1 (Th1) and/or Th17 cells and impaired their intestinal sequestration via p38-MAPK pathway. Alternatively, dietary short-chain FAs (SCFAs) expanded gut T regulatory (Treg) cells by suppression of the JNK1 and p38 pathway. We used experimental autoimmune encephalomyelitis (EAE) as a model of T cell-mediated autoimmunity to show that LCFAs consistently decreased SCFAs in the gut and exacerbated disease by expanding pathogenic Th1 and/or Th17 cell populations in the small intestine. Treatment with SCFAs ameliorated EAE and reduced axonal damage via long-lasting imprinting on lamina-propria-derived Treg cells. These data demonstrate a direct dietary impact on intestinal-specific, and subsequently central nervous system-specific, Th cell responses in autoimmunity, and thus might have therapeutic implications for autoimmune diseases such as multiple sclerosis.

INTRODUCTION

Renewed focus on the gut, the largest zone of interaction between the environment and the human organism, has opened new avenues for various fields of life sciences engaged in health and disease. A rapid and simultaneous paradigm shift in microbiologic diagnostics from classical culturing to next-generation sequencing has enabled a more precise estimation of the human gut microbiome composition under healthy conditions (Luzi et al., 2012). Consequently, there is fast-growing quest for possible disease associations involving interactions between diet, the gut, and microbiome components, especially in autoimmunity (e.g., diabetes and inflammatory bowel disease [IBD]) (Brown et al., 2013; Clemente et al., 2012).

In spite of many remaining questions regarding which components of the microbiome are critically responsible for the fine-tuning of adaptive immune responses in the gut, growing empirical evidence suggests that nutrition and bacterial metabolites might impact the systemic immune response in the context of disease and autoimmunity (Cotillard et al., 2013; Macia et al., 2012). Here, fatty acids (FAs), as an integral component of daily diet, have become a primary focus of investigation. Although extensive data on the effects of saturated FAs on the innate immune system exist from the field of cardiovascular disease, their impact on the players of the adaptive immune system is less well understood (Bhargava and Lee, 2012). Although the downstream mechanisms and the cellular mediators for the effect of SCFAs remain inconclusive, most data point to the involvement of regulatory immune mechanisms. For example, in models of IBD, gavage of various SCFAs leads to local...
expansion of intestinal T regulatory (Treg) cells (Smith et al., 2013; Furusawa et al., 2013), and microbiome analyses of a large cohort of affected individuals with type 2 diabetes revealed a lack of butyrate-producing bacteria, further underscoring the impact of FAs in health and disease (Qin et al., 2012).

The gut microbiome, along with various dietary habits such as high salt intake, has been recently established as an environmental contributor to the pathogenesis of multiple sclerosis (MS) (Berer et al., 2011; Kleinewietfeld et al., 2013), a T-cell-mediated autoimmune disease of the central nervous system (CNS) with neurodegenerative features (Haghikia et al., 2013). Previous interdisciplinary research has led to the contemporary view that the autoimmune basis of MS stems from an imbalance between pathogenic pro-inflammatory Th1 and/or Th17 cells and anti-inflammatory or regulatory mechanisms of immune cells including Treg cells (Kleinewietfeld and Hafler, 2014). Thus, the rationale of currently available therapeutic interventions is to suppress pathogenic Th1 and Th17 cells and/or to augment Treg cell differentiation (Haghikia et al., 2013).

Here, we show that dietary-induced changes in the gut shaped Th cell responses through the opposing effects of dietary SCFAs and the less-well-studied medium-chain (MC) FAs or LCFAs.

RESULTS

LCFAs Promote Polarization of Naive T Cells toward Th1 and Th17 Cells

To investigate effects of alkanoic acids on the differentiation of naive T cells under Th1 and Th17 cell polarizing conditions in vitro, we tested derivatives with different aliphatic chain lengths in murine CD4+ T cells (Figures 1A and 1B). At 250–500 µM, the C12 FA dodecanoic acid (lauric acid [LA]) increased differentiation of Th17 cells (Figure 1C) and Th1 cells (Figure 1D) by ~50% as compared to control conditions; LA decreased the differentiation of CD4+ T cells from healthy human donors also increased the differentiation of CD4+ T cells by about one third versus control (Figure 1E). Growth curves and apoptosis rates did not differ between controls and LA-treated cultures, indicating that LA acted to directly enhance T cell differentiation and did not merely affect T cell expansion or viability (Figures S1A–S1L). Expression analyses of differentiated T cell gene signatures revealed increased mRNA expression of Ifng, granulocyte macrophage colony-stimulating factor (Csf2), and tumor necrosis factor alpha (Tnf), but not interleukin-17A (Il17a) for Th1 cells (Figure S2A). Congruent analyses also revealed increased mRNA levels of Il17a, Csf2, Rorc, aryl hydrocarbon...
receptor (Ahr), Tbx21, Il23a, IL-23 receptor (Il23r), transforming growth factor beta (Tgfβ1), and Tnf, but not Ifng, in the presence of 250 μM LA versus control (Figure 2B), supporting the argument for an increased generation of Th17 cells after addition of LA in vitro. Treg cell quantitative real-time PCR (qRT-PCR) revealed a ~50% reduction of Foxp3 expression after addition of LA versus control in vitro (Figure 2C).

**Gene and Protein Expression Analyses Implicate Th17 Cell and MAPK Pathways as Modulators of LA Cellular Mechanism**

To further understand the differential effects of different FA lengths on T cell differentiation, we analyzed gene expression of the candidate fatty acid receptors liver X receptor alpha (Lxrα) and various G protein coupled receptors (Gpr40, Gpr41, Gpr43, Gpr84, Gpr119, and Gpr120) in different CD4+ T cell subsets. The presence of Gpr40, 41, 43, and 84 on the mRNA level was mostly confined to naive T cells. In contrast to previous reports (Smith et al., 2013), none of the receptors were detectable in Th17 cells or Treg cells, and only Gpr43 was present in Th1 cells. Lxra, Gpr119, and Gpr120 were not detected in any T cell subset (Figure 2D). Likewise, addition of the Toll-like receptor 1/2 agonist Pam3CSK4 to Th1, Th17, or Treg cell differentiation assays did not show any comparable effect to LA (not shown).

No additional increase of Th17 cell frequency was found subsequent to the addition of LA to dendritic cells (DCs) cocultured with LA-treated T cells, arguing for a direct effect of LA in fostering Th17 cell polarization (Figure 2A). In order to identify downstream signaling factors potentially involved in the LA effect on Th1 cell differentiation, we evaluated the transcriptome profile of in vitro, LA-treated versus -untreated Th1 and Th17 cells. Analyses of Th17 cells revealed Maf (c-Maf) as the highest differentially expressed gene (DEG), increasing 16.5-fold in LA- versus control-treated T cells (Figure 2B). Further DEGs pointing to induction of Th17 cell differentiation in multiple pathway analyses included the salt-sensing kinase Sgk1 and multiple MAPK family members, such as Mapk14 (encodes p38). The expression profile of Th1 cells revealed differential expression of critical Th1 cell genes, whereas changes in the MAPK family were not as prominent (not shown).

Because p38 MAPK-mediated signaling is a well-characterized integrator of environmental stressors, we tested the effects of FAs on p38 MAPK regulation. Expression analysis revealed a statistically significant ~13-fold increase in Mapk14 in Th17 cells, and to a lesser degree in Th1 cells, upon LA application (Figure 2C). At the post-transcriptional level, LA treatment of T cells under Th17-cell-polarizing conditions led to a significant increase of p38 phosphorylation (pp38, Figure 2D). Pharmacological inhibition of p38 MAPK via addition of the specific blocker SB202190 almost completely inhibited the effect of LA on Th17 or Th1 cell polarization (Figures 2E and 2F). Furthermore, genetic ablation of the p38α subunit via CD44-cre-mediated deletion in T cells completely abolished the enhanced Th17 and Th1 cell differentiation effect of LA (Figures 2G and 2H). Neither pharmacological inhibition nor genetic ablation of p38 led to increased cell death (not shown).

**SCFAs Promote Polarization of Naive T Cells toward Treg Cells**

Corresponding to the effect of FAs on Th1 and Th17 cell differentiation, we tested derivatives with different aliphatic chain lengths on naive T cells under Treg-cell-polarizing conditions (Figures 3A and 3B). Propionate (PA, C3:0) revealed the most significant effect on murine Treg cell differentiation in vitro at a concentration of 150 μM (Figure 3C). We further corroborated the Treg-cell-stimulating effect of PA in vitro in a human T cell differentiation assay. Therein, application of PA to healthy donor naive CD4+ T cells increased both the frequency of CD4+CD25+ Foxp3+ cells and, to a lesser extent, the proliferation of differentiated Treg cells (Figure 3D). Adding PA to human naive T cells under Th17-cell-polarizing conditions led to a significant reduction in the frequency of CD4+IL-17A+ T cells (Figure 3E).

Furthermore, ex vivo transcriptome analyses of Treg cells derived from PA-pre-treated mice and Treg cells from previously untreated mice revealed DEGs in the two different cell populations (Figure 3F). Through the use of multiple pathway analyses steps, rationally selected DEGs revealed, and qRT-PCR confirmed (Figure 3G), Lpin-2 (encodes lipin2) and Mapk8 interacting protein-2 (Mapk8ip2, encodes JIP2) as relevant, upregulated genes in Treg cells from PA-pre-treated mice. In contrast, LA treatment led to a downregulation of Lpin-2 expression in both Th1 and Treg cells; however, changes in Mapk8ip2 were not significant in both cell types. Furthermore, LA treatment had no effect on this pathway in Th17 cells. As previously shown, the increase of Lpin-2 led downstream to downregulation of JNK1 activation (encoded by Mapk8), which in turn is a key activator of pro-inflammatory transcription factors such as NF-κB. Relative mRNA expression of Mapk8 parallels that of Lpin-2 in all investigated cell types after LA application (Figures 3A–3C). At the post-transcriptional level, PA treatment of T cells led to an opposing effect on p38 phosphorylation (pp38, Figure 3H) compared to that which was exerted by LA on Th17 cells (Figure 2D).

**LA-Rich Diet Impacts Th1-Cell- and Th17-Cell-Mediated CNS Autoimmunity In Vivo**

The distinct in vitro effects of FAs on naive CD4+ cells prompted us to examine their effects in vivo using murine MOGns,55 EAE as a model of Th1-cell- and/or Th17-cell-mediated autoimmunity. Male C57BL/6 mice were fed standardized and otherwise completely matched diets rich in either LA (C12) or palmitic acid (PALM, C16) and were compared to mice on a control diet after EAE induction. Mice on the LA-rich diet did not display different body weights compared to controls (mean ± SEM on day 20 of EAE: 22.2 ± 0.5 g versus 23.8 ± 2.0 g, p = 0.96). Mice fed the LA-/PALM-rich diets displayed a more severe course of the disease (Figures 4A and 4A–4C), although disease incidence (12/13 ctrl. versus 10/10 LA) and mortality were unaffected. Upon ex vivo phenotyping by flow cytometry of the spinal cord infiltrates, the LA diet increased Th17 cell frequencies in the CNS on day 14 post immunization (p.i.) whereas Th1 cells (Figure 4B) and CD11b+ antigen-presenting cells (Figure 4C) remained unchanged.

Phenotyping of splenic T cells during EAE revealed an increase of Th1 and Th17 cell frequencies under an LA-rich diet on day 10 p.i. (Figure 4D). In parallel, an LA-rich diet expanded...
Figure 2. MAPK Pathways Are Modulators of LA Cellular Mechanism

LA Exerts Effect on Th17 Cells via the Small Intestine

In order to elucidate the anatomic site of the observed in vivo actions of LA, we examined LA concentrations in the serum, blood cells, the complete duodenum, and duodenal mucosa after either LA-rich or control diet on day 10 p.i. We found that LA concentrations in the blood compartment (Figure 5A), mucosa, and duodenum (Figure 5B) were significantly increased after LA diet, with the highest concentrations in the blood compartment and an enrichment of LA in the duodenal mucosa versus the complete duodenum. More extensive analysis of FAs in these compartments also revealed an increase of MCFAs and LCFAs of various chain lengths, especially C14–C18 under an LA diet (Figures S5A–S5D). Given the enrichment of LA in the small intestine (SI) mucosa, we further scrutinized the gut. In a kinetic analysis of intraepithelial lymphocytes (IELs), lamina propria lymphocytes (LPLs), and Peyr’s patches (PPs) in various gut locations, we found the most pronounced increase in IL-17A and IFN-γ on the protein level in LPLs of the SI 10 days p.i. (Figures 5C, 5D, S5E, and S5F). To monitor the dynamics of increased Th17 cell frequency under LA in EAE, we analyzed the SI more closely, quantifying Th17 cells in the SI LPLs between days 4 and 21 p.i. Ex vivo flow cytometry analysis of relative Th17 cell abundance in the SI LPLs on days 4, 7, 10, and 14 p.i. showed an initial increase of Th17 cells in SI LPLs, with a maximum at day 7 and a subsequent gradual reduction after day 10 (Figure 5E), coinciding with the onset of symptoms in EAE (Figure 4A). A cell transfer experiment on day 10 p.i. corroborated these data with an increased accumulation of MOG-activated, labeled T cells, specifically in the SI LPLs of LA-diet-fed mice (Figure 5F). Intestinal Treg cell frequencies were not affected (Figures S5G and S5H). The increase of Th17 cells was specific for MOG35-55-immunized mice; we did not observe any changes in Th17 cell frequency in naive control mice or mice 10 days p.i. with complete Freund’s adjuvant (CFA) only (Figure S5I).

To further investigate whether metabolites of the gut microbiota are involved in LA’s enhancing effect on Th17 cells, we added fecal filtrates from either LA- or control-diet mice to naive T cells under Th17-cell-polarizing conditions. The addition of fecal filtrates from LA-diet mice resulted in higher numbers of Th17 cells than from control diet (Figure 5G), arguing for the involvement of the local microbiome and their metabolic changes in the SI. Metabolite analyses revealed that not only were the longer-chain FAs increased under LA diet (Figures S5A–S5D), but levels of SCFAs and particularly PA were significantly decreased in the feces of LA-fed mice (Figure 5H), thus lending additional support for the crucial involvement of gut microbiota and metabolites in the effect of LA on Th17 cells.

We also performed a microbiome analysis of feces sampled on day 10 p.i. with MOG35-55 versus naive mice. Although EAE itself did not alter microbiome composition, the LA diet reduced Prevotellaceae and S24-7 families of the Bacteroidetes phylum as compared to controls (Figure 5I and Table S1).

Finally, for optimal investigation of LA-mediated microbial effects on intestinal Th17 cells in vivo, we employed the anti-CD3-specific antibody treatment model, which is characterized by an acute immune activation and a particular susceptibility of the SI to enhanced inflammation (Chatenoud and Bluestone, 2007; Esplugues et al., 2011). Usage of this model revealed a pronounced increase of Th17 cell frequency in SI IELs as compared to naive control mice (Figure S5J). In line with our data from the EAE model, we observed a further increase in IEL Th17 cell frequency under an LA-rich diet after anti-CD3 antibody injections (Figure S6K). This effect could be reproduced in vivo via oral transfer of feces from LA-diet-fed mice into germ-free (GF) recipients. These mice were found to have higher frequencies of Th17 cells in IELs as compared to control GF mice having received feces from mice under a control diet (Figure 5J). Further, gut microbiota were found to be necessary for the effect of LA on Th17 cell increase, as no Th17 cells were detectable in the SI after feeding only LA to control GF mice (Figure 5K).

In Vivo, PA-Mediated Treg Cell Regulatory Response Ameliorates CNS Autoimmunity

To evaluate whether the opposing effect of the C3 FA PA seen in vitro exerts an ameliorating effect on the course of EAE, we applied 150 mM PA (or water solvent) by daily oral gavage either (1) at the day of immunization (DI) or (2) at onset of disease (OD). In contrast to the LA-rich diet, application of PA revealed beneficial effects in EAE, but only in the preventive setting (Figure 6A). Ex vivo recall assays revealed a significant increase of the anti-inflammatory cytokine IL-10 in cells derived from PA-treated EAE, whereas, in contrast to LA-diet mice, no significant difference in IL-17A production was observed (Figure 6B). Phenotyping of SI LPLs on day 8 p.i. revealed increased CD4+CD25+Foxp3+ Treg cell frequency in PA-treated EAE mice (Figure 6C). Analyses of the signature cytokines in different gut sub-compartments also showed increased mRNA levels of Tgfβ1, Il10, and Foxp3 in the distal parts of the SI in these mice (Figure 6D). To test whether orally delivered PA imprints a protective phenotype on Treg cells in vivo, we transferred Treg cells derived from PA-pre-treated (7 days) or untreated (5 × 10^5 CD4+CD25+ Treg cells; i.p.) mice into recipient mice concurrently with EAE induction; flow cytometry analysis of isolated cells confirmed the congruity of Foxp3+ cell percentages in the transferred T cell preparations (69%–72% under both conditions). Treg cells derived from PA-pre-treated mice led to a marked improvement in the clinical course of the recipient EAE as compared to controls (Figure 6E). The improved clinical outcome in PA-DI-treated mice was reflected in the histopathological analyses of the spinal cord, with less inflammatory cell infiltration, less demyelination, and a higher degree of axonal preservation (Figure 6F).

**DISCUSSION**

Our data add FAs to the list of environmental triggers of T cell differentiation that might act as risk factors for Th1-cell- and/or
Figure 3. SCFAs Promote Polarization of Naive T Cells toward Treg Cells and Suppress the JNK1 and p38 Pathway

(legend continued on next page)
Th17-cell-mediated autoimmune diseases like MS (Kleijniewietfeld and Hafler, 2014). Recent epidemiological studies reveal that lifestyle factors such as smoking, obesity, and salt intake might constitute a risk for MS (Hedström et al., 2011, 2014; Kleijniewietfeld et al., 2013). Because such a diet is also typically rich in FAs, our present data offer important immunological and functional groundwork for epidemiological observations and identify saturated FAs as a new dietary, non-infectious trigger involved in intestinal T cell differentiation due to the interaction of gut-hosted microbiota and nutritional metabolites.

Here we show that, in autoimmune disease, FAs exert direct effects both on murine and human Th cells under polarizing conditions in vitro and in the context of antigen-specific T cell response in vivo. Treatment with SCFAs, PA most potently, enhanced differentiation and proliferation of CD4+CD25+Foxp3+ Treg cells and ameliorated EAE disease course. In contrast, MCFAs or LCFAs such as LA or PALM enhanced Th1 and Th17 cell differentiation and contributed to a more severe course of EAE. The simultaneous increase of tracked Th17 cells in the spleen and CNS together support a model of differential segregation of antigen-specific T cells under an LA-rich diet. This hypothesis is further supported by the increased levels of LA found in the blood and mucosa compartments in mice having received an LA-rich diet. The increase of LA in both compartments might explain not only the systemic effect of LA on Th17 cell differentiation in vivo, but also the increased frequency of Th17 cells in the lamina propria during the initial antigen-specific immune response in EAE.
The proposed FA-receptor mediating the aforementioned effects remains to be identified. The presented divergent effects of saturated FAs on Th1 and Th17 versus Treg cells depended on the length of the carbon chain backbone, thus arguing for a pattern- or chain length-sensing receptor on T cells. Here, GPR109 might be a critical player, as it has been recently shown for butyric acid (Singh et al., 2014), whereas receptors previously noted of importance, GPR41 and GPR43 (Kim et al., 2013), are not as relevant in our system. Given the plasticity of Th17 and Treg cells and their complex, divergent, intercellular signaling pathways during differentiation (review see Kleine-Wiebfeld and Hafler, 2014), it is likely that several mechanisms act in concert.

On both the gene expression and post-transcriptional levels (protein), members of the MAP kinase family, including p38 and JNK1, along with lipin-2 and their regulation of downstream pathways, are herein identified as crucial mediators of the effects of saturated FAs on T cells. Although both p38 and JNK1 have been shown to non-redundantly contribute to T cell death, differentiation, and proliferation (Rincón and Pedraza-Alva, 2003), p38-MAPK in particular is a well-known integrator of environmental stress and is involved in both T cell differentiation (Kleine-Wiebfeld et al., 2013) and models of MS (Kremenetsov et al., 2014; Noubade et al., 2011). Because p38-MAPK plays a prominent role in T cell development and function (Alam et al., 2014), it can be argued that developmental changes due to the genetic knock-out of p38-MAPK lead to future alterations of T cell differentiation prior to the application of FAs. However, pharmacological blockage of this pathway after T cell development confirmed its specific involvement in FA effects on T cell differentiation. Indeed, the coupling of both the p38 and JNK MAP kinase pathways to T cell receptor signaling might allow for lineage-specific signals in T cell differentiation (Flavell et al., 1999). Additionally, our identification of lipin-2 signaling in the PA-induced generation of Treg cells adds to previous literature whereby it has been shown to counteract the pro-inflammatory effects of saturated FAs on macrophages (Valdearcos et al., 2012), yet it had not been previously described in the context of T cells.

In addition to the MAP kinase family members, transcription factor c-Maf and kinase SGK1, both of which have been shown to be critically involved in Th17 cell differentiation (Tanaka et al., 2014; Wu et al., 2013), were among the differentially expressed genes identified in LA-treated T cells under Th17-cell-polarizing conditions.

In the absence of antigen, the expansion of Th17 cells in the SI of anti-CD3-treated mice clearly increased under LA feeding. Despite its limitations, especially in the context of CNS autoimmunity, the ability of anti-CD3 to induce acute immune activation offers a valuable setup to shed further light on the distribution of auto-antigen-specific Th cells under an LA-rich diet (Esplugues et al., 2011). Indeed, our observation of an increased influx of Th17 cells into the SI, e.g., the lamina propria, of LA-fed mice during EAE, provides evidence for the involvement of the SI, including nutritional metabolites and microbiota of the gut, in systemic T cell immune responses prior to T cell CNS infiltration.

The shift of the gut microbiome toward decreased Prevotella-ceae and Bacteroidetes after an LA-rich diet might partially explain the enhanced positive effect of fecal transplantations over diet manipulation. This concept is backed by the observed decrease in SCFAs in the gut under LA-rich diet along with recent reports implicating the pivotal role of Bacteroidetes in the fermentation of fiber-rich nutrition into SCFAs. Furthermore, a dysbiotic microbiome with lower proportions of Bacteroidetes has been associated with immune dysregulation and incidence of autoimmune disorders such as Crohn’s disease and asthma (Macia et al., 2012; Trompette et al., 2014).

Of particular interest is the ability of PA to beneficially influence the generation of Treg cells (Arpaia et al., 2013). Our study posits PA as a potent compound with the capacity to restrain CNS autoimmunity via restoration of the altered Treg cell:effector T cell balance, which is disturbed in MS patients (Vigiletta et al., 2004). So far, influencing MS via direct Treg cell manipulations, e.g., via superagonistic anti-CD28 antibodies, has been considered worthwhile (Beyersdorf et al., 2005) but not practically feasible outside of controlled experimental conditions (Hüning, 2012). In fact, PA is a common environmental compound that was traditionally part of many preservatives and is already ingested by many people at lower concentrations (Cummings et al., 1987). Given this wide range in everyday practice and

(H) Quantification of SCFAs in feces of mice on a control or LA diet on day 10 p.i. (n = 5 per group).
(I) Three comparing samples from mice on an LA-rich diet (inner rings) versus samples from mice on a control diet (outer rings). Feces were sampled on day 10 p.i. (n = 3 per group) and compared to samples from the same mice before induction of EAE (n = 3 per group).
(J and K) Ex vivo flow cytometry analysis of Th1 (J) and Th17 (K) cell frequencies in SI IELs and LPLs after anti-CD3 antibody injection and oral transfer of feces from LA-diet-fed mice into germ-free (GF) recipients as compared to control GF mice with transfer of feces from donor mice under a control diet. A representative contour plot is shown.
*p < 0.05, **p < 0.001. See also Figure S5.
Figure 6. PA Ameliorates CNS Autoimmunity via Induction of Treg Cells in the Small Intestine

(A) Clinical course of MOG 35-55 EAE. Mice received daily PA starting either at the day of immunization (DI, n = 15), at onset of disease (OD, n = 25), or the solvent water (controls, n = 29) via oral gavage in addition to the normal diet. Data are shown on a 5-point score scale pooled from three experiments.

(B) Cytokine measurement in cultures after ex vivo recall with MOG 35-55 (splenocytes harvested on day 8 p.i. of MOG 35-55 EAE, n = 8 versus 9 per group).

(C) Flow cytometry analysis of cells isolated from the LPLs of EAE either treated with PA (n = 5) or with water (untreated, n = 5) showing higher amount of T reg cells in PA-treated mice.

(D) Gene expression analyses of \texttt{tgf}b1, \texttt{il}10, and \texttt{foxp}3 in the SI LPLs of either PA (PA DI) or water (control) (triplicates, data pooled from seven to ten preparations).

(legend continued on next page)
growing evidence for the lasting dietary effect on microbiome composition (Cotillard et al., 2013), a rapid translation of PA therapy from pre-clinical studies to clinical trials in MS patients seems reasonable.

In sum, this study identifies dietary saturated FAs as crucial modulators in the gut, shifting Th1 and Th17 versus Treg cell balance in autoimmune neuroinflammation. We propose a dual mechanism of action for LA, comprising (1) increased Th17 and Th1 cell polarization and proliferation as a systemic effect and (2) enhanced sequestration of Th17 cells in the gut in the context of immune activation. Further studies in humans to explore the supplementary therapeutic potential of enriched diets are highly warranted.

**EXPERIMENTAL PROCEDURES**

**EAE and Diet**

For experiments under LA-rich diet, mice received a chow containing 30.9% crude fat rich in the MCFA C12:0 (lauric acid, 13.47%), and mice on a control diet were fed a chow with 4.2% crude fat. Mice were adapted to high-fat chow for 4 weeks before EAE induction. For EAE under LA, either 200 μL PA (150 mM) or solvent (water) were applied daily via oral gavage in addition to normal diet with 3.3% crude fat, at either day of immunization (DI) or onset of disease (OD). For transfer experiments, mice received either PA or water via oral gavage in addition to normal diet for 7 days before gut Treg cells were isolated and injected into EAE at DI.

For EAE, 8- to 11-week-old mice were anesthetized and subcutaneously injected with 200 μg MOG 35-55 and 200 μg CFA. Pertussis toxin (200 ng/mouse) was applied i.p. on days 0 and 2. Daily clinical evaluation was performed via a 5-point scale. All experiments were in accordance with the German laws for animal protection and were approved by the local ethic committees (Erlangen AZ 54-2532.1-56/12; Bochum AZ 84-02.04.2014.A104). For details and providers of materials used, see Supplemental Information.

**In Vitro MOG Restimulation Assay**

Splenocytes from EAE mice were obtained on day 10 p.i. and seeded at a density of 3 × 10^5 cells/ml in Re-medium. MOG 35-55 (1, 20, 100 μg/ml) and ConA (1.25 μg/ml) were added for stimulation, and cells were cultured for 48 hr. supernatants were harvested and analyzed for cytokines (ELISA). To monitor proliferation, cells were labeled with fixable proliferation dye (eBioscience) according to the manufacturer’s protocol.

**Cell Tracking Experiment**

Splenocytes from EAE mice were obtained on day 10 p.i., labeled with fixable e450 proliferation dye (eBioscience), and intravenously transferred into mice on a LA or control diet on day 10 p.i. (25 × 10^6 cells/mouse). Spleens, CNS, and SI of recipient mice were scrutinized on day 4 post cell transfer and analyzed by flow cytometry for CD4^+ e450^ cells.

**Free Fatty Acid Quantification**

Total fatty acid concentrations in plasma, whole blood cells, and duodenum of mice on a LA or control diet were analyzed on day 10 p.i. via gas chromatography (GC) as described (Ostermann et al., 2014). In brief, lipids were extracted with MTBE/MeOH and derivatized with methanolic hydrochloric acid, and the resulting FAME were quantified by GC with flame ionization detection. For details of SCFAs analyses in feces, see Supplemental Information.

**Microbiome Analysis**

Frozen DNA isolated from mice fecal sample with total masses ranging from 1.3 to 38.7 ng were stored at −20°C. The bacterial 16S rRNA genes were amplified (35 cycles) using the degenerate forward primer 5′-AGGTTGTGAT CMTGCGGTCAG-3′ and the non-degenerate reverse primer 5′-GGTTACCTTG TTACGACTT-3′. Each amplified product was concentrated via solid-phase reversible immobilization and quantified by electrophoresis using an Agilent cell staining kit according to the manufacturers’ protocol. For details and providers of materials used, see Supplemental Information.
Fecal Transplant
200 mg feces from mice on LA or control diet were collected in a sterile manner on the day of fecal transfer and re-suspended in 1 ml sterile filtered autoclaved tap water and adjusted to a final volume of 200 mg feces/ml, vortexed, and centrifuged. Each recipient mouse received 200 µl of fecal supernatant by oral gavage on 3 consecutive days before αCD3 injection (20 µg/mouse, 145-2C11, BD PharMingen) after 3 weeks of housing in sterile cages with sterile autoclaved water and autoclaved food.

Transcriptome Analysis
Total RNA was isolated from corresponding cells using the RNeasy Mini Kit (QIAGEN) with prior peqGOLD TriFast (Peqlab) treatment. cDNA was generated with Ambion WT Expression Kit (Life Technologies). Subsequently, Affymetrix Mouse Gene ST Arrays were processed by the manufacturer’s protocol. Data were processed with the Affymetrix Expression Console and Transcriptome Analysis Console v.2.0 (TAC) software, and candidate genes were selected rationed under consideration of both gene functions found in literature (NCBI and GeneCards) and integrative pathway analyses by Ingenuity Pathway Analysis (IPA, QIAGEN).

Statistical Analysis
Statistical analysis was performed with GraphPad Prism (GraphPad Software). All in vitro and ex vivo data were analyzed by one-way ANOVA followed by Tukey’s post test, unpaired t test, or Wilcoxon rank sum test after checking for normal distribution (unless indicated otherwise in the legends). EAE data by Kruskal-Wallis, and Mann-Whitney U test. Data are presented as mean ± SEM; *p < 0.05, **p < 0.01, or ***p < 0.001 were considered to be statistically significant.

SUPPLEMENTAL INFORMATION
Supplemental Information includes five figures, one table, and Supplemental Experimental Procedures (including isolation of CNS-infiltrating lymphocytes, splenic lymphocytes, immune cell analysis in the gut, immunohistochemistry and tissue staining, flow cytometry analysis, cytokine detection, real-time PCR, and immunoblotting) and can be found with this article online at http://dx.doi.org/10.1016/j.immuni.2015.09.007.

AUTHOR CONTRIBUTIONS
A. Haghikia and S.J. planned and performed experiments and analyses. A. Haghikia and R.A.L. designed the study and planned as well as supervised the research. A. Haghikia, S.J., and R.A.L. wrote the manuscript. R.G. designed the study, supervised the research, and edited the manuscript. A.D., J.B., J. T., and S.D. performed experiments. N.H.S., M.K., and D.N.M. analyzed the data and edited the manuscript.

ACKNOWLEDGMENTS
We wish to thank S. Seubert, K. Bitterer, and X. Pedreiturria for expert technical assistance. The authors also thank Megan Massa (B.A. Neuroscience) for editing the language of the manuscript. Cell sorting was supported by the FACS Core Unit, Nikolaus-Fiebig-Center, Friedrich-Alexander-University Erlangen, Germany. R.A.L. holds an endowed professorship supported by the Novartis Foundation. This study was supported by the Deutsche Forschungsgesellschaft (DFG) grant CRC128/22 (to R.G.).
